Kaimanovich and Vershik described certain finitely generated groups of exponential growth such that simple random walk on their Cayley graph escapes from the identity at a sublinear rate, or equivalently, all bounded harmonic functions on the Cayley graph are constant. Here we focus on a key example, called $G_1$ by Kaimanovich and Vershik, and show that inward-biased random walks on $G_1$ move outward faster than simple random walk. Indeed, they escape from the identity at a linear rate provided that the bias parameter is smaller than the growth rate of $G_1$. These walks can be viewed as random walks interacting with a dynamical environment on $\mathbb{Z}$. The proof uses potential theory to analyze a stationary environment as seen from the moving particle.

1. Introduction. The study of random walks and harmonic functions on finitely generated groups has a long history. For a random walk supported by a finite generating set, Avez (1974) showed that a necessary condition for the existence of non-constant bounded harmonic functions is the positivity of a quantity called the entropy of the random walk. Kaimanovich and Vershik (1983) and Derriennic (1980) showed that this condition is sufficient as well and extended it to more general random walks. A more natural quantity for probabilists is the speed (or rate of escape) of the random walk. By speed of a random walk $\langle X_n \rangle$ on the Cayley graph of a group, we mean $\lim_{n \to \infty} |X_n|/n$ (if the limit exists), where $|X_n|$ denotes the distance of $X_n$ from the identity element. It follows from the result of Avez that the existence of nonconstant bounded harmonic functions implies positive speed. Varopoulos (1985) established that, for finitary symmetric random walks, this is an equivalence. In particular, Varopoulos showed that the speed is zero on any group of subexponential growth. It is perhaps surprising that the converse is false; a particularly illuminating example of a Cayley graph of exponential growth on which simple random walk has zero entropy (and zero speed) was described by Kaimanovich and Vershik (1983). Random walks on this Cayley graph with bias toward the identity element will be the focus of the present article. These are not group-invariant random walks, but they do capture the growth rate of
the group: Lyons (1995) showed that such biased random walks on any Cayley graph are transient for all values of the bias less than the exponential growth rate of the group. Here, we prove the surprising result that this inward biasing can change the speed from zero to a positive number.

More precisely, for $\lambda > 0$, define the $\lambda$-biased random walk $\text{RW}_\lambda$ on a connected locally finite graph with a distinguished vertex $\Theta$ as the time-homogeneous Markov chain $(X_n; \ n \geq 0)$ with the following transition probabilities. The distance $|v|$ from a vertex $v$ to $\Theta$ is the number of edges on a shortest path joining the two vertices. Suppose that $v$ is a vertex of the graph. Let $v_1, \ldots, v_k \ (k \geq 1$ unless $v = \Theta)$ be the neighbors of $v$ at distance $|v| - 1$ from $\Theta$ and let $u_1, \ldots, u_j \ (j \geq 0)$ be the other neighbors of $v$. Then the transition probabilities are $p(v, v_i) = \lambda/(k\lambda + j)$ for $i = 1, \ldots, k$ and $p(v, u_i) = 1/(k\lambda + j)$ for $i = 1, \ldots, j$. This is a reversible Markov chain with edge weights (or conductances) $\lambda^{-n}$ on edges at distance $n$ from $\Theta$. Note that simple random walk, when all neighbors are equally likely, is the particular case $\lambda = 1$. In the special case of a Cayley graph, we take $\Theta$ to be the identity element. Define the growth rate of a finitely generated group $G$, denoted $\text{gr}\ G$, to be the limit as $n \to \infty$ of the $n$th root of the number of vertices in its Cayley graph at distance $n$ from $\Theta$. The result of Lyons (1995) mentioned above is that $\text{RW}_\lambda$ is transient for $\lambda < \text{gr}\ G$ and recurrent for $\lambda > \text{gr}\ G$. This may not be surprising if we think of the Cayley graph of $G$ as being something like spherically symmetric; after all, it is vertex transitive. However, this point of view is not well justified. For example, there are amenable groups of exponential growth; thus, the balls in these groups do not form Følner sets. For one such group, called $G_1$ by Kaimanovich and Vershik ([1983], Section 6.1), we show that the speed of $\text{RW}_\lambda$ is positive for $1 < \lambda < \text{gr}\ G_1 = \varphi := (1 + \sqrt{5})/2$, although it vanishes for $\lambda = 1$. This demonstrates how far this Cayley graph is from being spherically symmetric since on any spherically symmetric graph, the speed of $\text{RW}_\lambda$ is monotone decreasing (when it exists).

The group $G_1$, also known as the lamplighter group, is defined as a semidirect product $G_1 := \mathbb{Z} \rtimes \sum_{x \in \mathbb{Z}} \mathbb{Z}/2$ of $\mathbb{Z}$ with the direct sum of copies of $\mathbb{Z}/2$ indexed by $\mathbb{Z}$; for $m, \ m' \in \mathbb{Z}$ and $\eta, \ \eta' \in \sum_{x \in \mathbb{Z}} \mathbb{Z}/2$, the group operation is

$$(m, \eta)(m', \eta') := (m + m', \ \eta \oplus J^{-m} \eta'),$$

where $J$ is the left shift, $J(\eta)(j) := \eta(j + 1)$, and $\oplus$ is componentwise addition modulo 2. We call an element $\eta \in \sum_{x \in \mathbb{Z}} \mathbb{Z}/2$ a configuration and call $\eta(k)$ the bit at $k$. We identify $\mathbb{Z}/2$ with $\{0, 1\}$. The first component of an element $x = (m, \eta) \in G_1$ is called the position of the marker in the state $x$, denoted $M(x)$. Generators of $G_1$ are $(1, 0), (-1, 0)$ and $(0, 1_0)$. The reason for the name of this group is that we may think of a streetlamp at each integer with the configuration $\eta$ representing which lights are on, namely, those where $\eta = 1$. We also may imagine a lamplighter at the position of the marker. The first two generators of $G_1$ correspond to the lamplighter taking a step either to the right or to the left (leaving the lights unchanged); the third generator corresponds to flipping the light at the position of the lamplighter. See Figure 1.
Simple random walk on $G_1$ thus corresponds to the marker moving according to simple random walk on $\mathbb{Z}$ with delays one-third of the time when it changes the bit at its location. However, RW$_\lambda$ is quite different in that the configuration influences the transition probabilities of the marker as a random walk on $\mathbb{Z}$. Namely, for $\lambda > 1$, there is a tendency for the walk to return to the initial state $\Theta$, which means that the marker has a greater tendency to change bits to 0 than to 1. In order to do so, rather than head for the origin, the marker heads for the bit equal to 1 that is on the same side of the origin as the marker and is most extreme since this is a shortest path back to $\Theta$.

**Theorem 1.1.** Whenever $1 < \lambda < \phi$, the speed of RW$_\lambda$ on $G_1$ is a.s. a strictly positive constant. In fact, a lower bound for the speed is given by

$$\lim_{n \to \infty} \frac{|X_n|}{n} \geq \lim_{n \to \infty} \frac{|M(X_n)|}{n} \geq \frac{(\lambda - 1)(\sqrt{\lambda + 1} - \lambda)}{3\lambda(2 + \lambda)(1 + \lambda - \sqrt{\lambda + 1})} > 0 \quad \text{a.s.}$$

See Figure 2 for a graph of the lower bound. As a corollary, we see that for RW$_\lambda$ with $1 < \lambda < \phi$, there are nonconstant bounded harmonic functions on $G_1$, for example, the function whose value at $x$ is the probability that the bit at the origin is eventually 0 given that the random walk starts at $x$.

A crucial element in the proof of Theorem 1.1 is the one-dimensionality of the underlying space $\mathbb{Z}$. This allows an easy determination of the shortest paths from $\Theta$ to any element of $G_1$, so that the transition probabilities for RW$_\lambda$ admit simple expressions in terms of the configuration; see below. In contrast, the higher-dimensional analogues of $G_1$ require the solution of a traveling-salesman problem to determine the transition probabilities of RW$_\lambda$ and it is unknown whether the speed is still positive.

Coming back to the one-dimensional situation, consider outward-biased random walks on $G_1$, that is, RW$_\lambda$ for $0 < \lambda < 1$. Surprisingly, these escape from the identity even more slowly than simple random walk.

**Proposition 1.2.** Whenever $0 < \lambda < 1$, the speed of RW$_\lambda$ on $G_1$ is a.s. 0. In fact,

$$\liminf_{n \to \infty} \frac{|X_n|}{\log n} > 0 \quad \text{and} \quad \limsup_{n \to \infty} \frac{|X_n|}{\log n} < \infty \quad \text{a.s.}$$
This is much easier to prove than Theorem 1.1; see Section 4. Also, it follows from standard shift-coupling techniques that the only bounded harmonic functions are the constants when $0 < \lambda < 1$.

To make explicit the distances and transition probabilities on $G_1$, define

\[(1.1) \quad \text{flag}_R := \sup\{k \geq 0; \eta(k) = 1\} \quad \text{and} \quad \text{flag}_L := \inf\{k \leq 0; \eta(k) = 1\}.\]

We call these the right and left flags; note that when $\eta(k) = 0$ for all $k \geq 0$, we have $\text{flag}_R = -\infty$ and similarly for $\text{flag}_L$. When $m \geq 0$, we have

\[(1.2) \quad |(m, \eta)| = 2|\text{flag}_L \wedge 0| + m + 2(\text{flag}_R - m)^+ + \sum_{k \in \mathbb{Z}} \eta(k)\]

and similarly when $m < 0$. The transition probabilities are as follows for the case $m \geq 0$; the case $m < 0$ is symmetric. First, we have $p(\Theta, x) = 1/3$ for all the generators $x$ of $G_1$. If $(m, \eta) \neq \Theta$ and $\text{flag}_R < m$, then $p((m, \eta), (m - 1, \eta)) = \lambda/(\lambda + 2)$ and

\[p((m, \eta), (m + 1, \eta)) = p((m, \eta), (m, \eta + 1_m)) = 1/(\lambda + 2).\]

If $\text{flag}_R = m$, then $p((m, \eta), (m, \eta + 1_m)) = \lambda/(\lambda + 2)$ and the other transition probabilities are $1/(\lambda + 2)$. Finally, if $m < \text{flag}_R$ and $\eta(m) = 0$, then $p((m, \eta), (m + 1, \eta)) = \lambda/(\lambda + 2)$ and the other transition probabilities are $1/(\lambda + 2)$, while if $\eta(m) = 1$, then

\[p((m, \eta), (m + 1, \eta)) = p((m, \eta), (m, \eta + 1_m)) = \lambda/(2\lambda + 1)\]

and

\[p((m, \eta), (m - 1, \eta)) = 1/(2\lambda + 1).\]

Thus, $\text{RW}_\lambda$ on $G_1$ can be studied directly as a random walk interacting with a dynamical environment on $\mathbb{Z}$, without any reference to the group structure. However, the only proof we know that establishes positivity of speed for all $\lambda \in$
(1, \phi) uses explicitly the structure of the Cayley graph. Simpler comparison arguments are available to show positivity of speed for \lambda in the smaller range (1, 1.5).

2. The Fibonacci tree and semitightness. In this section, we begin our analysis of the dynamics of RW_\lambda. We first obtain a lower bound on the escape probability from \Theta by using a subtree of the Cayley graph. This is then given a ‘stationary’ version. Next, we prove that the marker is unlikely to be much closer to the origin than are the flags and, finally, that when the marker is at a flag, the expected time until a flag separates the marker from the origin is finite.

We first define a subgraph of G_1, which is a tree rooted at \Theta. The vertices consist of states \(x = (m, \eta)\) for which \(m \geq \text{flag}_R(x)\) and \(\eta(k) = 0\) for all \(k < 0\). Each vertex \((m, \eta)\) with \(\text{flag}_R(m, \eta) = m\) has the single child \((m + 1, \eta)\) and each vertex \((m, \eta)\) with \(\text{flag}_R(m, \eta) < m\) has the two children \((m + 1, \eta)\) and \((m, \eta \oplus 1_m)\). This is called the Fibonacci tree (see Figure 3). Since the number of vertices at distance \(n\) from the root of the Fibonacci tree is asymptotically a constant times \(\phi^n\), this shows that \(\text{gr} G_1 \geq \phi\). From this, it is not hard to see that an upper bound for the number of vertices at distance \(n\) from \Theta in the Cayley graph of \(G_1\) is a constant times \(\sum_{k \leq n} \phi^k\), which, again, is just asymptotically a constant times \(\phi^n\). Hence, \(\text{gr} G_1 = \phi\).

Transience of RW_\lambda implies that \(\limsup |M(X_n)| = \infty\), but it does not immediately imply that \(\lim |M(X_n)|\) exists. In fact, this limit does exist when \(1 < \lambda < \phi\), so that the marker tends either to \(\infty\) or to \(-\infty\). These cases are clearly symmetric and it is convenient to deal with them separately by removing a half line. Thus, define the subset \(G_1^+ \subseteq G_1\) to be the set of \((m, \eta)\) such that \(m \geq 0\) and \(\eta(j) = 0\) for all \(j < 0\). Observe that for any \(x \in G_1^+\), the shortest paths connecting \(x\) to \(\Theta\) in \(G_1\) are contained in \(G_1^+\). Thus RW_\lambda on \(G_1^+\) has the same transitions as RW_\lambda on \(G_1\) except that transitions where the marker moves to \(-1\) are suppressed. We use the method of Lyons (1995) to show that RW_\lambda is transient on \(G_1^+\).

![Fig. 3. The Fibonacci tree.](image-url)
Lemma 2.1. Assume that $1 < \lambda < \varphi$. The probability that $RW_\lambda$ on $G_1^+$, started from $\Theta$, never returns to $\Theta$ is at least $h(\lambda)$, where

$$h(\lambda) := \frac{\sqrt{\lambda + 1} - \lambda}{2(1 + \lambda - \sqrt{\lambda + 1})} > 0.$$ 

In particular, $RW_\lambda$ is transient on $G_1^+$.

Proof. Observe that the Fibonacci tree is also a subgraph of $G_1^+$. Let $C$ denote the effective conductance of the Fibonacci tree from the root to infinity. Observe that if $v$ in generation $n$ has two children, then the effective conductance from $v$ to infinity in the descendant subtree rooted at $v$ is $1/C$. Since the edges incident to $2$ have conductance 1, the obvious recursions of the Fibonacci tree and the usual series-parallel laws give the equation

$$C = \sum \frac{1}{C} + \frac{1}{1 + \lambda/C}.$$ 

Since the Fibonacci tree is subperiodic, $C > 0$ for $\lambda < \varphi$ by Lyons (1990), whence the unique positive solution is

$$C(\lambda) = \frac{\sqrt{\lambda + 1} - \lambda}{1 + \lambda - \sqrt{\lambda + 1}}.$$ 

By Rayleigh’s monotonicity principle [see Doyle and Snell (1984)], the effective conductance from $\Theta$ to infinity in $G_1^+$ is at least the conductance on any subgraph, hence at least $C(\lambda)$. The escape probability of $RW_\lambda$ on $G_1^+$ from $\Theta$, that is, the probability that the random walk never returns to $\Theta$, is at least $C(\lambda)$ divided by the total conductance incident to $\Theta$ (see Doyle and Snell); the latter is 2, which proves the lemma. \qed

We are interested in looking at the configuration from the viewpoint of the marker in order to find a stationary measure and thus be able to use ergodic theory. Now, after a long time, $RW_\lambda$ on $G_1^+$ will be far right of the root and many bits will be 1. In order to allow (in the limit) infinitely many 1’s to the left of the marker, define the space $\Gamma \supseteq G_1 \supseteq G_1^+$ to be the set of $(m, \eta) \in \mathbb{Z} \times \{0, 1\}^\mathbb{Z}$ such that $\sum_{j=0}^{\infty} \eta(j) < \infty$. Let $RW_\lambda(\infty)$ denote the Markov chain on $\Gamma$ obtained by ignoring the left flag and not assigning any special status to the origin of $\mathbb{Z}$. More precisely, define flag := sup$(k \in \mathbb{Z}; \ \eta(k) = 1)$. The transitions give relative weights 1 for the marker moving away from the flag, $\lambda$ for the marker moving toward the flag and $\lambda^\eta(m)$ for flipping the bit at the marker.

Lemma 2.2. For $k \in \mathbb{Z}$, let

$$A_k := \{x \in \Gamma; \ \text{flag}(x) < M(x) \leq k\}.$$ 

Suppose that $(Y_0, Y_1, \ldots)$ is the Markov chain $RW_\lambda(\infty)$ started from any initial state with flag$(Y_0) < M(Y_0)$. Then

$$P[Y_n \notin A_{M(Y_0)} \text{ for all } n > 0] \geq \frac{2}{2 + \lambda} h(\lambda).$$
PROOF. Without loss of generality, we may assume that \( M(Y_0) = 0 \). Define the map \( Q: \Gamma \to G_1^+ \) by
\[
Q(m, \eta) := (\max\{m, 0\}, \eta 1_{[0, \infty)}).
\]
Observe that \( Q(Y_n) \) will sometimes remain constant, but that the (possibly finite) sequence of successive changes of state will have the distribution of \( RW_\lambda \).

It is evident that if \( Y_n \in A_0 \), then \( Q(Y_n) = Q(Y_0) \). Therefore, the event \( \{Y_n \notin A_0 \text{ for all } n > 0\} \) contains the event \( \{Q(Y_n) \neq Q(Y_0) \text{ for all } n > 0\} \). Conditional on \( \{Q(Y_1) \neq Q(Y_0)\} \), the probability of \( \{Q(Y_n) \neq Q(Y_0) \text{ for all } n > 0\} \) is at least \( h(\lambda) \) by Lemma 2.1. Thus
\[
\mathbb{P}[Y_n \notin A_0 \text{ for all } n > 0] \geq h(\lambda) \mathbb{P}[Q(Y_1) \neq Q(Y_0)]
\]
\[
= \frac{2}{2 + \lambda} h(\lambda). \tag*{\square}
\]

We now establish the semitightness property that the marker is unlikely to be far to the left of the flag. Let \( \mathcal{F}_n := \sigma(Y_0, \ldots, Y_n) \).

**Lemma 2.3.** Let \( \langle Y_n \rangle \) be the Markov chain \( RW_\lambda^{(-\infty)} \) and \( D_n := \text{flag}(Y_n) - M(Y_n) \). If \( D_0 = 0 \), then for any \( n, k \geq 1 \) and \( 1 < \lambda < \varphi \),
\[
\mathbb{P}[D_n = k] \leq \lambda^{-(k-1)/2} \frac{1 + 2\lambda}{(\sqrt{\lambda} - 1)^2}.
\]

**Proof.** For any \( r \geq 0 \), let \( \tau_r := \min\{n \geq r; D_n \leq 0\} \). Set \( \beta := (1 + 2\lambda)/(\lambda + 2\sqrt{\lambda}) > 1 \) and define
\[
V_n := (\sqrt{\lambda})^{D_n} \beta^n.
\]
We show that \( \{V_{n \land \tau_r}; n \geq r\} \) is a supermartingale. Observe that \( |D_{n+1} - D_n| \leq 1 \) as long as \( D_n > 0 \). Let \( p_+^{(n)} \) and \( p_-^{(n)} \) denote the conditional probabilities of \( D_n \), respectively, increasing by one and decreasing by one conditional on \( \mathcal{F}_n \). Then for \( r \leq n < \tau_r \),
\[
\mathbb{E}[V_{(n+1) \land \tau_r} \mid \mathcal{F}_n] = \mathbb{E}[V_{n+1} \mid \mathcal{F}_n] = \beta V_n \left[ 1 + (\sqrt{\lambda} - 1) p_+^{(n)} + \left( \frac{1}{\sqrt{\lambda}} - 1 \right) p_-^{(n)} \right]
\]
\[
\leq \beta V_n \left( 1 + \frac{\sqrt{\lambda} - 1 + ((1/\sqrt{\lambda}) - 1)\lambda}{1 + 2\lambda} \right) = V_n = V_{n \land \tau_r},
\]
since the numerator is negative and the only possibilities for the vector \((p_+^{(n)}, p_-^{(n)})\) are \((1 + 2\lambda)^{-1}(1, \lambda)\) or \((2 + \lambda)^{-1}(1, \lambda)\).

It follows that on the event \( D_r = 1 \) and for \( n \geq r \),
\[
\mathbb{E}[V_{n \land \tau_r} \mid \mathcal{F}_r] \leq V_r = \sqrt{\lambda} \beta^r
\]
and therefore by Markov’s inequality,
\begin{equation}
\Pr[D_n = k, \tau_r \geq n | F_r] \leq \Pr[V_{n\wedge \tau_r} = \lambda^{k/2} \beta^\nu | F_r] \leq \lambda^{-(k-1)/2} \beta^{-(n-r)}
\end{equation}
on \{D_r = 1\}. Now decomposing the event \(\{D_n = k\}\) according to the last \(r\) such that \(D_r = 1\), we get
\[\Pr[D_n = k] = \sum_{r=1}^{n} \Pr[D_n = k, \max\{j \leq n; D_j = 1\} = r].\]
The \(r\)th summand is at most the right-hand side of (2.2), and summing over \(r\) yields the desired bound since \(1/(1 - \beta^{-1}) = (1 + 2\lambda)/\sqrt{\lambda - 1}\).

Finally, we show that when the marker is at the flag, the time until the marker is to the right of the flag has finite mean.

**Lemma 2.4.** Let \((Y_n)\) be the Markov chain \(RW^{(-\infty)}_{\lambda}\) with \(M(Y_0) = \text{flag}(Y_0)\). If \(\tau\) is the first time that \(M(Y_{\tau}) > \text{flag}(Y_{\tau})\), then
\[E[\tau] \leq \frac{1 + 2\lambda}{\lambda - 1}.
\]
**Proof.** Set \(\hat{D}_n := \max(\text{flag}(Y_n) - M(Y_n), -1)\). Note that for \(n < \tau\), we have
\[E[\hat{D}_{n+1} | F_n] \leq \hat{D}_n - \frac{\lambda - 1}{1 + 2\lambda}.
\]
Let
\[W_n := \hat{D}_n + \frac{\lambda - 1}{1 + 2\lambda} n.
\]
Then \(\{W_{n\wedge \tau}; n \geq 0\}\) is a supermartingale. By the optional stopping theorem [see Durrett (1991), Theorem 7.6], we get that
\[0 \geq E[W_{\tau}] = E[\hat{D}_{\tau}] + \frac{\lambda - 1}{1 + 2\lambda} E[\tau] = -1 + \frac{\lambda - 1}{1 + 2\lambda} E[\tau]. \]

**3. Proof of Theorem 1.1.** We are now in a position to look at the configuration from the viewpoint of the marker. Recall that \(\mathcal{S}\) denotes the left shift operator on \(\{0, 1\}^\mathbb{Z}\). Let \(\Gamma^*: \{\eta; \sum_{j>0} \eta(j) < \infty\}\) and \(\text{flag}^*(\eta) := \sup\{k \in \mathbb{Z}; \eta(k) = 1\}\). Define \(\mathcal{S}^*: \Gamma \to \Gamma^*\) by
\[\mathcal{S}^*(m, \eta) := \mathcal{S}^m(\eta)\]
and set \(\xi_n := \mathcal{S}^*(Y_n)\). Define
\[\Delta_n := M(Y_n) - M(Y_{n-1}) \in \{-1, 0, 1\}\]
for \(n \geq 1\) and \(\Delta_0 := 0\), say. Observe that \(\{(\xi_n, \Delta_n); n \geq 0\}\) is a Markov chain.
The transition probability kernel for \((\xi_n, \Delta_n)\) is denoted \(K^*_\lambda(\cdot, \cdot)\) and may be described as follows. When \(\xi_n(0) = 0\),

\[
\Delta_{n+1} = \begin{cases} 
\text{sign(flag}^*(\xi_n)), & \text{with probability } \lambda/(2 + \lambda), \\
-\text{sign(flag}^*(\xi_n)), & \text{with probability } 1/(2 + \lambda), \\
0, & \text{with probability } 1/(2 + \lambda).
\end{cases}
\]

When \(\xi_n(0) = 1\) and flag\(^*(\xi_n) = 0\),

\[
\Delta_{n+1} = \begin{cases} 
1, & \text{with probability } 1/(2 + \lambda), \\
-1, & \text{with probability } 1/(2 + \lambda), \\
0, & \text{with probability } \lambda/(2 + \lambda),
\end{cases}
\]

and when \(\xi_n(0) = 1\) but flag\(^*(\xi_n) > 0\),

\[
\Delta_{n+1} = \begin{cases} 
1, & \text{with probability } \lambda/(1 + 2\lambda), \\
-1, & \text{with probability } 1/(1 + 2\lambda), \\
0, & \text{with probability } \lambda/(1 + 2\lambda).
\end{cases}
\]

Finally,

\[
(3.1) \quad \xi_{n+1} = \begin{cases} 
\mathcal{S}_{\Delta_{n+1}} \xi_n, & \text{if } \Delta_{n+1} = \pm 1, \\
\xi_n \oplus 1_0, & \text{if } \Delta_{n+1} = 0.
\end{cases}
\]

Note that \(\mathcal{S}^*\) takes the set \(\{\text{flag}(x) < M(x)\}\) to the set \(\{\text{flag}^* < 0\}\). Suppose that flag\(^*(\xi_0) < 0\). Let \(n(k)\) be the \(k\)th return time of the sequence \(\langle \xi_j \rangle\) to \(\{\text{flag}^* < 0\}\) and

\[
Z_k := \sum_{j=1}^{n(k)} \Delta_j = M(Y_{n(k)}) - M(Y_0).
\]

If \(Z_k \leq 0\), then \(Y_{n(k)} \in A_{M(Y_0)}\). It follows from Lemma 2.2 that from any initial state with flag\(^* < 0\),

\[
(3.2) \quad P[Z_k > 0 \text{ for all } k > 0] \geq \frac{2h(\lambda)}{2 + \lambda}.
\]

Now assume that flag\(^*(\xi_0) = 0\). Equip \(\Gamma^* \times \{-1, 0, 1\}\) with the metric

\[
d((\eta, \delta), (\eta', \delta')) := |\delta - \delta'| + \sum_{j=-\infty}^{\infty} 2^j |\eta(j) - \eta'(j)|.
\]

With this metric, for any \(j_0\), the set \(\{((\eta, \delta); \forall j > j_0, \eta(j) = 0)\}\) is compact. By Lemma 2.3, it follows that the laws of \((\xi_n, \Delta_n)\) are tight. Thus, the Cesàro averages \(n^{-1} \sum_{j=1}^{n} \text{law}(\xi_n, \Delta_n)\) are tight and have a subsequential weak\(^*\) limit \(\pi_0\). Since the transition probabilities \(K^*_\lambda\) are continuous, \(\pi_0\) must be stationary for \(K^*_\lambda\). Passing to an ergodic component yields a stationary ergodic Markov chain \((K^*_\lambda, \pi)\) [Rosenblatt (1971)]. Inducing the Markov system \((K^*_\lambda, \pi)\) on the subset \(\{\text{flag}^* < 0\}\) of the state space [see Petersen (1983)] yields a measure \(\pi'\) for which the increments \(Z_{k+1} - Z_k\) form a stationary ergodic sequence.
A little thought shows that $Z_{k+1} - Z_k$ is either $-1$, $0$ or $1$. Let $R_k$ denote the cardinality of the range $\{Z_1, \ldots, Z_k\}$. From (3.2), it follows that

$$
\lim_{k \to \infty} Z_k/k = \lim_{k \to \infty} R_k/k = \mathbf{P}_\pi[Z_k \neq 0 \text{ for all } k > 0] \quad \text{a.s.,}
$$

where the second equality uses Theorem 6.3.1 of Durrett (1991). Hence by the ergodic theorem and (3.2),

$$
\mathbf{E}_\pi[Z_2 - Z_1] \geq \frac{2h(\lambda)}{2 + \lambda}.
$$

By the tower proof of Kac’s lemma [Petersen (1983)], we have

$$
\mathbf{E}_\pi[\Delta_1] = \pi\{\text{flag}^* < 0\} \mathbf{E}_\pi[Z_2 - Z_1].
$$

By Kac's lemma itself, the reciprocal of $\pi\{\text{flag}^* < 0\}$ is the expected return time to $\{\text{flag}^* < 0\}$. If the return time is not 1, then $\text{flag}^*(\xi_1) = 0$ and the expected additional time needed to return to $\{\text{flag}^* < 0\}$ is, by Lemma 2.4, at most $(1 + 2\lambda)/(\lambda - 1)$. Hence the total expected return time is bounded by $1 + (1 + 2\lambda)/(\lambda - 1) = 3\lambda/(\lambda - 1)$. Combined with (3.4), this yields

$$
s_\lambda := \mathbf{E}_\pi[\Delta_1] \geq \frac{2(\lambda - 1)}{3\lambda(2 + \lambda)} h(\lambda).
$$

Note that this is the lower bound in the statement of Theorem 1.1.

Let $p_0$ be the probability that $\text{RW}_\lambda$ in $G^+_1$ started from $(1, 0)$ does not return to the infinite set of states where the marker is at the origin. By the obvious coupling to $G^+_1$, the probability that the partial sums $\sum_{j=1}^n \Delta_j$ remain positive is $p_0$, starting from any state in $\{\text{flag}^* < 0\}$. To see that $p_0 > 0$, let

$$
T := \inf \left\{ n \geq 1; \sum_{j=1}^n \Delta_j \leq 0 \right\},
$$

which corresponds on $\Gamma$ to the first time that the marker is not to the right of its starting point. According to the maximal ergodic lemma [Durrett (1991), Theorem 6.2.2],

$$
\mathbf{E}_\pi[\Delta_1 \mathbf{1}_{\{T = \infty\}}] \leq 0,
$$

whence $p_0 = \mathbf{P}[T = \infty] > 0$ by (3.5).

We use this to transfer the bound (3.5) to $G_1$ by coupling $\text{RW}_\lambda$ on $G_1$ to the Markov chain $K^*_\lambda$ on $\Gamma^*$ with initial distribution $\pi$ conditioned on $\{\text{flag}^* < 0\}$. Let $\langle X_0, X_1, \ldots \rangle$ be the Markov chain $\text{RW}_\lambda$ on $G_1$ starting from any state with $M(X_0) > \text{flag}_p(X_0) \geq 0$, and define

$$
\tilde{T} := \inf \{ n \geq 1; M(X_n) \leq M(X_0) \}.
$$

Let $(\xi_0, \Delta_0)$ have the conditional distribution $(\pi | \text{flag}^*(\xi_0) < 0)$. For $1 \leq n < \tilde{T}$, define $\Delta_n := M(X_n) - M(X_{n-1})$. This produces by (3.1) a sequence $\langle \xi_n; \ 0 \leq n < \tilde{T} \rangle$; if $\tilde{T}$ is finite, then continue the chain $(\xi_n, \Delta_n)$ independently
by using the kernel $K^*_\lambda$. Note that with this coupling, $T = \tilde{T}$, and in particular, $\mathbb{P}[\tilde{T} = \infty] = p_0$. Thus, on the event $\{\tilde{T} = \infty\}$, the speed of the marker equals

$$\lim_{n \to \infty} \frac{M(X_n)}{n} = \lim_{n \to \infty} \frac{1}{n} \sum_{j=1}^{n} \Delta_j = \mathbb{E}_{\pi}[\Delta_1] = s_\lambda \quad \text{a.s.}$$  

by the ergodic theorem.

Let $N(k)$ be the first $n > k$ such that

$$M(X_n) > \text{flag}_R(X_n) \geq 0 \quad \text{or} \quad M(X_n) < \text{flag}_L(X_n) \leq 0.$$  

Then $N(k) < \infty$ a.s. and by the coupling argument of the preceding paragraph,

$$\mathbb{P}\left[ \lim_{n \to \infty} |M(X_n)|/n = s_\lambda \mid X_0, X_1, \ldots, X_{N(k)} \right] \geq p_0.$$  

Therefore the speed of the marker equals $s_\lambda$ almost surely by the Lévy 0–1 law.

We calculate the speed $s'_\lambda$ of RW$_\lambda$ by using (1.2) and the above coupling. Let

$$U_n := (\xi_n(0) - \xi_{n-1}(0))1_{\{\Delta_n = 0\}}.$$  

Let $X_n = (M(X_n), \eta_n)$ be the Markov chain RW$_\lambda$ on $G_1$ starting from any state with $M(X_0) > \text{flag}_R(X_0) \geq 0$. On the event $\{\tilde{T} = \infty\}$, the coupling gives

$$\frac{1}{n} \sum_{k \in \mathbb{Z}} \eta_n(k) = \frac{1}{n} \sum_{k \in \mathbb{Z}} \eta_0(k) + \frac{1}{n} \sum_{i=1}^{n} U_i \to \mathbb{E}_\pi[U_1] \quad \text{a.s.}$$  

as $n \to \infty$ by the ergodic theorem. The bound in Lemma 2.3 and the Borel–Cantelli lemma imply that

$$\frac{1}{n}(\text{flag}_R(X_n) - M(X_n))^+ \to 0 \quad \text{a.s.}$$  

Combining equations (1.2), (3.6), (3.7) and (3.8), we arrive at

$$\lim_{n \to \infty} |X_n|/n = s_\lambda + \mathbb{E}_\pi[U_1] =: s'_\lambda$$  

a.s. on $\{\tilde{T} = \infty\}$. Using symmetry and the Lévy 0–1 law as before shows that this equation is strictly positive. We omit the argument.

**Remark.** An alternative expression for $\mathbb{E}_\pi[U_1]$ is $\mathbb{E}_\pi[\xi_0(0)1_{\{T=\infty\}}]$, which shows that this expectation is strictly positive. We omit the argument.

4. **Continuity of speed and outward-biased random walks.**

**Proposition 4.1.** Both almost sure limits

$$s_\lambda = \lim_{n \to \infty} |M(X_n)|/n \quad \text{and} \quad s'_\lambda = \lim_{n \to \infty} |X_n|/n$$

are continuous for $\lambda \in [1, \varphi)$. As $\lambda \uparrow \varphi$, both speeds tend to 0.
Note that by the criterion of Nash-Williams (1959), $\text{RW}_\varphi$ is recurrent.

**Proof.** The continuity at $\lambda = 1$ follows from the trivial bounds

$$s'_\lambda \leq 2s_\lambda = 2\mathbb{E}_\varphi [M(X_1) - M(X_0)] \leq \frac{2\lambda - 1}{1 + 2\lambda}.$$ 

For the continuity at points in $(1, \varphi)$, we need to make explicit the dependence of $\pi_\lambda$ on $\lambda$, so denote the stationary measures by $\pi_{\lambda, \nu}$. It follows from the positivity of $s_\lambda$ that these measures are unique, but we do not need that fact. Instead, we may rely simply on the fact that $s_\lambda$ and $s'_\lambda$ are the same for all stationary measures, since they have the values determined on $G_1$. By Lemma 2.3, any collection $\{ \pi_\lambda; \lambda_0 < \lambda < \varphi \}$ is tight. Since $K_1^\ast$ is continuous in $\lambda$, it follows that as $\lambda \to \lambda_0 \in (1, \varphi)$, the measures $\pi_{\lambda, \nu}$ have a weak*-limit point $\pi_{\lambda_0, \nu}$ on $\Gamma^\ast$ which is $K_1^\ast$-stationary. Therefore, $s_\lambda \to s_{\lambda_0}$ and $s'_\lambda \to s'_{\lambda_0}$ by the definitions (3.5) and (3.9).

The proof that the speeds tend to $0$ as $\lambda \uparrow \varphi$ requires another approach. As above, it suffices to show that the speed of the marker $s_\lambda \to 0$ as $\lambda \uparrow \varphi$. Now this speed can be estimated in $L^\ast$ by inducing on the set $\{ \text{flag}^* < 0 \}$. Recall that $Z_k$ denotes the change in position of the marker after $k$ visits to $\{ \text{flag}^* < 0 \}$. From (3.3), we have

$$s_\lambda \leq \lim_{k \to \infty} \frac{Z_k}{k} = P_{\pi}[Z_k \neq 0 \text{ for all } k > 0].$$

Checking the definitions shows that this last probability equals the probability for $\text{RW}_\lambda$ to escape from $\Theta$ in $G_1^\ast$. By Doyle and Snell (1984), this escape probability is the ratio of the effective conductance from $\Theta$ to infinity divided by the sum of the conductances incident to $\Theta$. We bound the effective conductance by shorting all vertices at the same distance from $\Theta$ [see Doyle and Snell (1984), Chapter 6]. The shorted graph is equivalent to a graph on $\mathbb{N}$ with the edge conductance between $n$ and $n + 1$ equal to $\lambda^{-n}$ times the number of edges in $G_1^\ast$ at distance $n$ from $\Theta$. Since this last number is at most $c\varphi^n$ for some constant $c$, the effective resistance is at least

$$\sum_{n \geq 0} \frac{(\lambda/\varphi)^n}{c} = \frac{\varphi}{c(\varphi - \lambda)}.$$ 

This finally gives the bound

$$s_\lambda \leq \frac{c(\varphi - \lambda)}{2\varphi}.$$ 

We now turn to outward-biased random walks on $G_1$ and show that they escape at a logarithmic rate from the identity.

**Proof of Proposition 1.2.** It suffices to show this on $G_1^\ast$. Let $L_k$ be the position of the marker after it has moved $k$ times. This stochastically dominates an asymmetric simple random walk on $\mathbb{N}$, where the latter has probability $\lambda/(1 + \lambda)$ of moving to the right. The expected time for the asymmetric
walk to reach \( l \) is \( O(\lambda^{-l}) \) [see Chung (1960), page 65]. Therefore, the same is true for \( \langle L_k \rangle \), whence the Borel–Cantelli lemma shows that
\[
\liminf_k \frac{\max\{L_j; j \leq k\}}{\log k} > 0 \quad \text{a.s.}
\]
Since the flag grows linearly in \( \max\{L_j; j \leq k\} \), the lower bound of the proposition follows.

For the upper bound, note that from an initial state \((0, \eta)\) with \( \eta(j) = 1 \) and \( j \geq 1 \), the number of visits of the marker to 0 before the first visit to \( j \) is geometric with mean at least \( c\lambda^{-j} \) for some positive constant \( c \). Therefore, from any state \((j, \eta)\), the time until the marker is at \( j + 1 \) is at least \( c\lambda^{-j} \) with probability bounded below by some \( \alpha > 0 \), since the probability is bounded below that the next state has \( \eta(j) = 1 \) and subsequently the marker visits 0 before returning to \( j \).

Consequently, the probability that the marker reaches \( k \) from \( k - \sqrt{k} \) in less than \( c\lambda^{-(k-\sqrt{k})} \) steps is at most \( (1-\alpha)^{\sqrt{k}} \). The Borel–Cantelli lemma then yields that
\[
\limsup_{n \to \infty} \frac{M(X_n)}{\log n} < \infty \quad \text{a.s.}
\]
This completes the proof (on \( G_1^+ \)). \( \square \)

**Remark.** The above argument shows that \( \limsup_{n \to \infty} M(X_n)/\log n = 1/|\log \lambda| \) a.s.

**Questions:** The groups \( G_k \), defined like \( G_1 \) but with \( \mathbb{Z}^k \) in place of \( \mathbb{Z} \), also play an important role in Kaimanovich and Vershik (1983): for \( k \geq 3 \), these yielded the first examples of a symmetric finitary measure on an amenable group which admits nonconstant bounded harmonic functions. The speed of simple random walk on \( G_k \) is 0 iff \( k \leq 2 \). Is it true that the speed of RW\( _\lambda \) is positive on \( G_k \) for \( 1 < \lambda < \text{gr } G_k \)? What can one say about the asymptotic shape of the configuration on \( G_k \)? Is the speed of RW\( _\lambda \) positive for \( 1 < \lambda < \text{gr } G \) when \( G \) is an arbitrary finitely generated group?

**Acknowledgment.** We are grateful to Vadim Kaimanovich for useful comments.
